Publication Title:

Electrostatic generating machines

Abstract:

Abstract of GB643579

643,579. Electrostatic machines. CENTRE NATIONAL DE LA RECHERCHE SCIENTIFIQUE. July 15, 1947, No. 18870. Convention date, July 17, 1946. [Class 35] A cylindrical type electrostatic generator enclosed in a gas-filled container 13 comprises a stator with an even number of part-cylindrical conducting segments 3, 4 and a rotor carrying outwardly facing part-cylindrical conducting members corresponding to those on the stator, the rotating conductors being divided into at least two longitudinally separated groups, each group forming a rotor of the machine, one providing excitation for the other. In the form shown, where two rotors are used, the conducting segments 7<SP>1</SP>, 8<SP>1</SP> provide excitation through brushes 11<SP>1</SP>, 12<SP>1</SP> for the stationary segment 3 which in turn influences the main rotor segments 7, 8, these being connected in turn by brushes 11, 12 to feed the other stationary segment 4 and the output lead 14. The insulating rotor cores 5, 5<SP>1</SP> supporting the rotor segments, also carry contact sectors 9, 10 and 9<SP>1</SP>, 10<SP>1</SP> respectively, these sectors being of substantially less angular extent than the rotor segments. The active edges of the stator and rotor segments are of rounded form and have a marginal thickness equal to at least two-thirds of the gas space between stationary and rotatable members. The capacity between rotor segments is reduced by using an insulator of low dielectric constant and cutting it away round the active edges. In a modification, the machine has two auxiliary rotors connected in succession and the machine may have several pairs of segments on the stator and rotor. Specification 637,434 is referred to.

COMPLETE SPECIFICATION

Electrostatic Generating Machines

We, CENTRE NATIONAL DE LA RECHERCHE SCIENTIFIQUE, of 13, Quai Anatole France (formerly called 13, Quai d'Orsay), Paris, France, a French National Public Administration, do hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:—

The present invention relates to electrostatic generating machines and particularly to such machines having a small power.

In Specification No. 637,434 there has already been described an electrostatic machine comprising relatively movable conducting members the active parts of which, contrary to the machines heretofore built, have a substantial thickness, the shape of said parts being chosen so as to provide for a good distribution of the electrostatic field, i.e. so that the said field remains, at each point of the surface of said parts, lower than or at most equal to the dielectric strength of the insulating medium in contact with said surface.

The present invention consists in an electrostatic generating machine comprising a gas-tight casing containing a compressed gas of high dielectric strength within which are disposed a principal rotor and at least one auxiliary rotor which are rotatable relative to a stator common to the rotors, said rotors each comprising an even number of part-cylindrical conducting segments which are movable relative to and face an even number of part-cylindrical conducting segments forming the stator, and electric connections including brush contacts for alternately connecting the segments of the principal rotor to a point of the machine having a substantially constant potential during normal operation of the machine and to an output lead, and simultaneously alternately connecting the corresponding aligned segments of the auxiliary rotor to one of the conducting segments of the

stator and to a point of the machine having a substantially constant potential during normal operation of the machine.

According to a feature of the invention, the active edges of the segments of the principal rotor and the active edges of the segments of the stator at least where they face the segments of the principal rotor, have a marginal thickness equal to at least two-thirds of the space between the segments of the principal rotor and the stator when said segments are at least partially facing each other.

The invention also consists in an electrostatic generating machine comprising a frame formed of a pair of spaced insulating flanges, stationary conducting members disposed between said spaced insulating flanges formed of an even number of part-cylindrical segments, a shaft rotatably mounted in said frame, at least one core composed of an insulating material secured to said shaft and rotatable therewith, a main series of part-cylindrical segments equal in number to and facing the first mentioned stationary part-cylindrical segments and disposed about said core and movable therewith, each of said main series of movable segments being connected to a corresponding conductive sector cooperating with an even number of fixed brushes, a gas-tight metallic casing enclosing said machine, an insulated output lead passing through said casing, electrical connections between said casing and the alternate, odd-numbered brushes and between alternate, even-numbered brushes and said output lead, and at least one auxiliary series of similar part-cylindrical segments aligned with the main movable segments and rotatable therewith but electrically separated therefrom, each of said auxiliary segments being connected to a corresponding conducting sector cooperating with another even number of fixed brushes, the alternate odd-numbered brushes being connected with one of the stationary segments and the alternate

even-numbered brushes being connected to said casing, the active edges of the main movable conducting segments constituting a principal rotor and the active edges of the stationary conducting segments, at least where they face the main movable segments, having a marginal thickness equal to at least two-thirds the space between a stationary conducting segment and a movable segment of the principal rotor when said segments are at least partially facing each other.

Two embodiments of a machine according to the invention are described hereafter with reference to the accompanying drawings, in which:—

Figure 1 is a diagrammatic longitudinal sectional view of a generating machine according to the invention and comprising a single auxiliary rotor;

Figure 2 is a sectional view along the line II—II of Figure 1;

Figure 3 is a sectional view along the line III—III of Figure 1;

Figure 4 is a sectional view similar to that of Figure 1 of a machine comprising two auxiliary rotors;

Figure 5 is a sectional view along the line V—V of Figure 4;

Figures 6, 7 and 8 are partial transverse sectional views showing different suitable shapes for the stationary and movable conducting members of machines according to the invention.

The stationary parts of the generating machine comprise two flanges 1 and 2 made of insulating material and carrying conducting members or segments 3 and 4, of part-cylindrical shape made, for instance of metal. Said conducting members delimit a cylindrical space inside which the rotating members are located. The latter comprise a main rotor which supplies the electric energy for the output load and one or more secondary or auxiliary rotors fastened on the same shaft and supplying the electrical energy for the excitation of the machine.

The main rotor comprises an insulating member of cylindrical shape 5 fastened on a shaft 6 and carrying two outwardly facing conducting members or segments 7 and 8, of part-cylindrical shape, for instance, made of metal. Said conducting segments which are the electricity conveyors of the machine are connected electrically with conducting sectors 9 and 10 on which rub conducting brushes 11 and 12, one of which is connected with the body of the apparatus, consisting in a gas-tight metallic cylindrical casing 13 which is filled with compressed gas, and the other of which is connected with an insulated output lead 14 for collecting the current supplied by the generating

machine. These electric connections are effected by conductors 15 and 16 which may be, for example, wires having a sufficient diameter.

The secondary rotor or rotors comprise similar members, with a difference in size only, their dimensions being generally smaller. In the following description the corresponding members of the secondary rotors and of the main rotor will bear the same references which will be primed in the case of the secondary rotors.

One of the features of the invention resides in the fact that the stationary conducting members 3 and 4 and the conveyors 7 and 8 have, at least on their active edges, a marginal thickness at least equal to two thirds of the thickness of the layer of gas separating a stationary conducting member from a conveyor when two such members are at least partially face to face with one another and the difference of potential between said members has the highest value it can have during a normal working cycle of the machine. On another hand, in order to avoid unfavourable losses through sparks, brush discharges, corona and the like, the said active edges are shaped, in a manner known *per se*, so as to provide for a good distribution of the electrostatic field, as above mentioned. The maximum power is thus obtained, which is determined by the respective capacities of the stationary and movable conducting members; the dielectric strength of the compressed gas and the above mentioned gas thickness.

It will generally be advisable to give the stationary conducting members and the movable conducting members or conveyors a marginal thickness which is substantially equal to or larger than the above mentioned gas thickness, their active edges being, for instance, shaped as shown in Figure 6. Any thickness may be chosen for the regions of the conducting members away from the edges. If this thickness is chosen smaller than the necessary marginal thickness it will be necessary to thicken the member progressively as the active edges are approached, as shown in sectional view in Figure 7. If, on the contrary, the general thickness of the conducting members is chosen higher than the necessary marginal thickness, it is sufficient to give the edges a favourable shape such as that which is shown in sectional view in Figure 8. These rules relate, more particularly, to the main rotor and the stationary conducting members 3 and 4 in the regions where they are opposite said main rotor; when the auxiliary rotors are to supply only an insignificant power, as is generally the case, it is not necessary that said rules be

applied strictly to the same. It will be necessary, however, to give the conveyors 7', 8', 7'', 8'' a sufficient marginal thickness comparable with that which is given 5 to the main conveyors 7 and 8.

In the particular embodiment shown in Figures 1 to 3, the stationary conducting member 4 is connected to the delivery brush 12 by the wire 16 and to the insulated output lead 14 by a direct connection. Brush 12' is connected to the stationary conducting member 3 by the wire 16' and the two brushes 11 and 11' are connected to the casing 13 by the 15 wires 15 and 15'.

If $2U$ is the maximum difference of potential which can exist, during a normal working, between the stationary conducting members 3 and 4 and the conveyors 7 and 8 when two of such members register at least partially, the stationary conducting member 3 is brought to a potential near $\pm U$ and acts as an inductor while the other stationary member 4 acts 25 as a shield.

Under the influence of the stationary conducting member 3, the main conveyor 7 and 8 acquire charges during their rotation, through brush 11 and sectors 9 and 10, the sign of which is opposite to that of 3. The conveyors carry away said charges when the contact is broken between the sectors and the brush 11 and their potential then rises in absolute 35 value. They afterwards come into contact with the brush 12 through sectors 9 and 10 and transfer their charges to the output lead 14 through the conducting chain formed of the members 12, 16, 4 and 14, which transfer is promoted by the conducting member 4 serving as a shield, after which the cycle is repeated.

The auxiliary rotor works in the same manner, but, in this case, conducting 45 member 4 plays the part of an inductor inducing a charge on the conveyors 7' and 8' when the latter are connected to the casing 13 by the wire 15', the brush 11' and the conducting sectors 9' and 10' connected with the conveyors 7' and 8', while the member 3 now plays the part of a shield promoting the discharge of the conveyors 7' and 8' and receiving the electricity carried by said conveyors, 55 through the brush 12' and the wire 16' which connects said brush 12' with the member 3. The secondary rotor thus constitutes, in a well known manner, an auxiliary generating machine which maintains the charge of conducting member 3 with a supply of electricity which compensates the losses sustained by said machine and, moreover, the whole 60 machine is spontaneously electrified as soon as it is rotated, thus insuring the

starting of the generating function.

It is advisable to give the conducting sectors 9, 10, 9', 10' on which the brushes rub a convenient angular opening (i.e. the angle subtended by the sector at the axis of rotation) and to give the brushes a convenient position in order that contact between the sector and brush will make, when the generating machine is in normal working action, at the moment 75 when the difference of potential between the sector and brush is near zero. Thus sparks are avoided which are unfavourable to the good preservation of the apparatus, as well as dissipation of electric energy which is prejudicial to the efficiency of the generator. For obtaining this result it is advisable to give the sectors an angular opening of the order of half the angle subtended at the machine axis by a conveyor, that is to say about 80° to 90° . When the stray capacities are comparatively important, as is the case more particularly in the auxiliary rotor, it is advisable to take a smaller angular opening, 50° to 70° for example. 80

It is possible, without departing from the scope of the invention, to choose, for the stationary conducting members 3 and 4 and the movable conducting members 7, 8, 7' and 8' an angular opening different from 180° while always giving them a substantially cylindrical surface. It is possible, for instance, to give them an opening of $180^\circ/n$ with $2n$ stationary conducting members in all and $2n$ conveyors on the principal rotor. The stationary conducting members may be connected electrically two by two so as to form two 105 groups serving the same purposes as the segments 3 and 4. The same will be true for the conveyors of each rotor. It will be advisable to give the conducting sectors on which the brushes rub an angular opening of about $180^\circ/n$. 110

In the construction of the main rotor it is advisable to reduce as much as possible the stray capacities between shaft and conveyors as well as between the conveyors themselves, for said capacities 115 reduce the power in an appreciable manner. To this end, it is important to use for the construction of the core 5 an insulating material the dielectric constant of which is as low as possible and preferably lower than 4 and to hollow out this insulator as much as possible consistent with its mechanical strength. 120

The generating machine shown at Figures 4 and 5 comprises, besides the principal rotor formed of the core 5 and the conveyors 7 and 8, two auxiliary rotors formed respectively of the cores 5' and 5'' and the conveyors 7' and 8', on 125 130

one hand, and 7¹¹ and 8¹¹ on the other. The brushes 11 and 12 co-operating with the principal rotor are connected respectively, by wires 15 and 16, with the gas-tight conducting casing 13 and with the insulated output lead 14. The brushes 11¹ and 12¹ co-operating with the first auxiliary rotor are connected respectively, by wires 15¹ and 16¹, with the casing 13 and with the stationary conducting member 3. Finally, the brushes 11¹¹ and 12¹¹ co-operating with the second auxiliary rotor are connected respectively, by wires 15¹¹ and 16¹¹, with the casing 13 and with the stationary conducting member 4.

When the machine is in operation, the stationary conducting member 3 is brought to a potential of around $\pm U$, 2U having the same signification as above while the other stationary member 4 is brought to a potential near $\mp 2U$. Under the influence of member 3 the conveyors 7 and 8 of the main rotor acquire through sectors 9 and 10 and the brush 11 a charge the sign of which is the reverse of that of the charge of member 3. They carry said charge away when the contact with brush 11 is broken and then come into relation with the brush 12 connected with the insulated output lead 14, transfer their charge through the latter to the output load, and then acquire from the same a charge of the opposite sign owing to the influence of member 4. This charge is carried away by the conveyors 7 and 8 when their relation with 12 is broken and then transferred to the body of the machine through brush 11, and the cycle is repeated.

The secondary rotors work in a similar manner. For one of them, the member 4 which plays the part of an inductor, inducing a charge on the conveyors 7¹ and 8¹ when the latter are connected with the casing 13 through brush 11¹ while member 3 plays the part of a shield for said conveyors; promoting their discharge when they are in contact with the brush 12¹ connected with member 3. This auxiliary rotor thus constitutes an auxiliary generating machine which maintains the charge of member 3 through a supply of electricity. For the other auxiliary rotor, the member 3 plays the part of an inductor inducing a charge on the conveyors 7¹¹ and 8¹¹ when they are connected to the casing 13 through the brush¹¹, while member 4 plays the part of a shield promoting the discharge of the conveyors 7¹¹ and 8¹¹ when they are in relation with brush 12¹¹ connected with member 4. This auxiliary rotor thus constitutes a generating machine which maintains the charge of member 4. It

would also be possible, instead of taking the charge of the conveyors 7¹¹ and 8¹¹ from the casing, to take it from the insulated output lead 14 of the generating machine.

It will be advisable, as in the previously described embodiment and for the same reasons, to give the conducting sectors 9 and 10 of the main rotor and the sectors 9¹, 10¹, 9¹¹ and 10¹¹ of the secondary rotors on which the brushes rub a suitable angular opening. It is also necessary to give the brushes a convenient position in order that during the usual working of the generating machine the contact between a sector and a brush is established at the moment when the potential difference between the sector and brush is near zero. In order to obtain this result it is advisable to give the sectors of the main rotor an angular opening equal to about two thirds of the angle covered by a conveyor, that is to say, 110° to 120° in the case of Figures 4 and 5. As regards the sectors 9¹, 10¹, 9¹¹, 10¹¹ of the secondary rotors it will be necessary to give them a generally more reduced opening, more particularly when stray capacities play an important part.

As previously, it will be possible to use, without departing from the scope of the invention, a number of stationary conducting members and/or conveyors exceeding two. It will also be convenient to reduce, as much as possible, the stray capacities of the main rotor.

Having now particularly described and ascertained the nature of our said invention and in what manner the same is to be performed, we declare that what we claim is:—

1. An electrostatic generating machine comprising a gas-tight casing containing a compressed gas of high dielectric strength within which are disposed a principal rotor and at least one auxiliary rotor which are rotatable relative to a stator common to the rotors, said rotors each comprising an even number of part-cylindrical conducting segments which are movable relative to and face an even number of part-cylindrical conducting segments forming the stator, and electric connections including brush contacts for alternately connecting the segments of the principal rotor to a point of the machine having a substantially constant potential during normal operation of the machine and to an output lead, and simultaneously alternately connecting the corresponding aligned segments of the auxiliary rotor to one of the conducting segments of the stator and to a point of the machine having a substantially constant potential during normal operation of the machine.

2. Machine as claimed in claim 1, wherein the active edges of the segments of the principal rotor and the active edges of the segments of the stator, at least where they face the segments of the principal rotor, have a marginal thickness equal to at least two-thirds of the space between the segments of the principal rotor and the stator when said segments are at least partially facing each other.
3. An electrostatic generating machine comprising a frame formed of a pair of spaced insulating flanges formed of an ducting members disposed between said spaced insulating flanges formed of an even number of part-cylindrical segments, a shaft rotatably mounted in said frame, at least one core composed of an insulating material secured to said shaft and rotatable therewith, a main series of part-cylindrical segments equal in number to and facing the first-mentioned stationary part-cylindrical segments and disposed about said core and movable therewith, each of said main series of movable segments being connected to a corresponding conductive sector cooperating with an even number of fixed brushes, a gas-tight metallic casing enclosing said machine, an insulated output lead passing through said casing, electrical connections between said casing and the alternate, odd-numbered brushes and between alternate, even-numbered brushes and said output lead, and at least one auxiliary series of similar part-cylindrical segments aligned with the main movable segments and rotatable therewith but electrically separated therefrom, each of said auxiliary segments being connected to a corresponding conducting sector cooperating with another even number of fixed brushes, the alternate odd-numbered brushes being connected with one of the stationary segments and the alternate even-numbered brushes being connected to said casing, the active edges of the main movable conducting segments constituting a principal rotor and the active edges of the stationary conducting segments, at least where they face the main movable segments, having a marginal thickness equal to at least two-thirds the space between a stationary conducting segment and a movable segment of the principal rotor when said segments are at least partially facing each other.
4. An electrostatic machine according to claims 1, 2 or 3, including at least four stationary conducting segments and four movable conducting segments for the principal rotor and in which every other pair of conducting segments belonging to the same group is electrically connected together, to provide that group with two functionally similar series of segments.
5. An electrostatic machine according to any of the preceding claims, in which the active edges of the principal movable conducting segments have a predetermined shape for maintaining the electrostatic field, at each point of the surface of said edges, not greater than the dielectric strength of the insulating medium in contact with said surface at said point.
6. An electrostatic machine according to any of the preceding claims, in which the active edges of the movable conducting segments have a thickness of the same order of magnitude as that of the principal movable conducting segments.
7. An electrostatic machine according to any of the preceding claims 3 to 6, in which the conducting sectors connected with each movable conducting segment are given such an angular opening, and the brushes such a position, that the contact between each sector and each brush is established at the moment when the difference of potential between a sector and a brush is near zero.
8. An electrostatic machine according to claim 7, in which there is only a single auxiliary rotor and in which the angular opening of the conducting sectors connected with each movable conducting segment is at most of the order of half the angular opening of the corresponding conducting segment and preferably less than said value when stray capacities are important.
9. An electrostatic machine according to claim 7, in which there are two auxiliary rotors and in which the angular opening of the conducting sectors connected with each movable conducting segment is at most of the order of two thirds of the angular opening of the corresponding conducting segment and preferably less than said value when stray capacities are important.
10. An electrostatic machine according to any of the claims 1 to 8 in which there is only a single auxiliary rotor, and in which the brush co-operating with the principal rotor and which is not connected to the body of the machine is connected to the output lead through one of the stationary conducting segments.
11. An electrostatic generating machine constructed and adapted to operate substantially as hereinbefore described with reference to Figs. 1, 2 and 3 of the accompanying drawings.
12. An electrostatic generating machine

constructed and adapted to operate substantially as hereinbefore described with reference to Figs. 4 and 5 of the accompanying drawings.
